ABSTRACT

New Giant Magneto-Impedance structures are studied both experimentally and theoretically. These transducers are made with one or two anisotropic nanocrystalline ribbons and the magnetic excitation is provided by coils mounted either in transverse or longitudinal direction. Very high sensitivities up to 1000V/T have been achieved even at low excitation frequencies from 5kHz to 500kHz and low consumption driving current (5-10mA). The Eddy current phenomenon and magnetic domain considerations are used to determine a semi-theoretical model of impedance. Intrinsic sensitivity computation approach emphasizes on the role of the differential magnetic permeability in coiled GMI detection performances.

KEYWORDS

Coiled GMI, intrinsic sensitivity, differential magnetic permeability,

1. INTRODUCTION

Since the work of Harrison et al [1] on the Eddy current in ferromagnetic wire modified by a DC magnetic field, the GMI effect has been the subject of many experimental and theoretical studies. In those studies [1-2], the authors have reported the physics background considering the dispersion of electromagnetic waves inside magnetic wire and sandwich transducer. By using micro magnetic theory the susceptibility tensor has been deduced in the case of the anisotropic magnetic core and combined with the impedance expression where the skin effect is often considered to be the main element responsible of the GMI ratio. From these works, fundamental analysis criteria were brought out such as the GMI ratio, the anisotropic magnetic H_k field and the AC permeability in the case of the direction configuration corresponding to the AC field perpendicular to the DC field. In this configuration, the impedance curve shows even parity form with the DC field and resonant magnetic field appears at H_k . However, odd curve impedance was also obtained in anisotropic material [3] by measuring the induced voltage through a pick-up coil in a GMI sandwich while the excitation was connected to the end of the copper conductor inside it. In this context, coiled GMI transducers benefits from the two components of the diagonal differential magnetic permeability components by using longitudinal or transverse coils [4]. One of the main advantages of coils is, for an identical excitation current, to

increase the magnetic excitation and finally the intrinsic sensitivity S_{int} which is the relevant parameter for weak magnetic field measurements [5].

Fig 1: GMI with one and two ferromagnetic ribbons and a transverse coil.

Fig 2: GMI with one and two ferromagnetic ribbons and a longitudinal coil.

By considering that the coiled GMI, with conductive ferromagnetic ribbon, exploits only self-induction behaviour (without eddy current because of low frequencies driving current), we express the coil output signal as an auto-induced voltage as written in relation (1). In this expression R_0 is the air reluctance of the coil, μ_{diff} represents the differential magnetic permeability at the DC field coordinate H_0 and I_{exc} is the driving current.

$$V_{gmi} = j\omega R_0 \left(\mu_{diff}(H_0) + \left(\frac{\partial \mu_{diff}}{\partial H_{ext}} \right)_{H_0} dh \right) I_{exc} \quad (1)$$

By writing (1) we assume that the measured magnetic field dh is proportional to the derivative of differential permeability. Relation (1) reminds the signal output of Search Coil and Fluxgate sensors. Nevertheless, a difference is noticeable from the first type because the DC field is naturally undetectable by a coil and also from the second type because coiled GMI have linear working behavior from the driving current. Thus, the coiled GMI principle is a part of the differential magnetic permeability variation described by R.M. Bozorth [6] as the so-called reversible or incremental permeability. To confirm this principle and determine optimum parameters, experimental studies have been done by measuring impedance and intrinsic sensitivity in low frequency range and DC field

range from 0A/m to $H_{max}= 2100\text{A/m}$. However, the experimental investigations presented are limited to the transverse coiled with one ribbon and the longitudinal coiled with two ribbons. In the purpose of the magnetometer design it is convenient to have an analytic formula for the impedance and the intrinsic sensitivity. Then, from the experimental studies, the differential magnetic permeability has been deduced for the transverse sample and the micro magnetic approach has confirmed the model presented.

2. EXPERIMENT

These transducers have identical magnetic ribbon of $20\mu\text{m}$ thick, 2cm wide and 10cm long and the coils both have 60 turns of insulated copper wound around the magnetic layer. The experimental work consists in measuring intrinsic sensitivity rather than the MI ratio by using a power spectrum analyzer with an AM modulation method measurement [5] that provides a direct measurement of the intrinsic sensitivity. Then a solenoid coil was used to generate the DC field H_0 and a pair of Helmholtz coils to produce the low frequency magnetic field dh of $1.2\mu\text{T}$. Phase modulation also occurs in output signal $V_{gmi}(t)$ but it remains less than amplitude modulation in this frequency range.

3. RESULTS

Effect of the longitudinal DC field

Figure 3 and Figure 4 show impedance results from the transverse and longitudinal coil. As sandwich GMI, coiled GMI impedance exhibit even parity curve but the decrease with respect to the DC field is greatly pronounced. The experimental MI ratios are, respectively, approximately 433% and 666% while maximum intrinsic sensitivities are 0.17 Ohms/A/m and 0.1 Ohms/A/m (Figure 5 and Figure 6). Thus, MI ratio provides information on strong magnetic field behaviour while intrinsic sensitivity provides information on weak magnetic field behaviour. Careful examination of intrinsic sensitivity curve shows that the greatest value of S_{int} occurs at the same H_0 coordinate and just at the beginning of the decrease of the impedance, resulting in the maximum derivative of magnetic permeability being located at this point. This coordinate corresponds to the anisotropic magnetic field H_k which is related to the ribbon shape with respect to the DC field and the magneto-crystalline anisotropy. Moreover, the two coiled GMI show different impedance $Z(H_0)$ curve shape, in particular a monotonous decrease for the transverse GMI which does not exhibit peak impedance as the longitudinal GMI does. These different behaviours suggest that only uniform magnetization rotation occurs in the transverse configuration whereas for longitudinal configuration, the walls' displacement dictates magnetization below H_k and rotation above it.

Fig 3: Transverse coiled GMI with one ribbon: Impedance with DC field at different frequencies.

Fig 4: Longitudinal coiled GMI with two ferromagnetic ribbons: Impedance with DC field at different frequencies.

Effect of the electric current frequency

Owing to inductive behaviour, impedance $Z(f)$ and intrinsic sensitivity $S_{int}(f)$ change with a linearity curve until $f=200\text{ kHz}$ for a DC field equal to H_k (Figure 7). As frequency increases, intrinsic sensitivity (Figure 8) reaches its maximum value at 800 kHz and begins to decrease at 1MHz . The impedance becomes less inductive but more resistive. Eddy currents are developing more and more and GMI becomes less sensitive in relation to the weak DC field (Figure 9). However, strong DC field H_{max} removes the intrinsic sensitivity and the impedance becomes again inductive which means Eddy currents are removed [2] inside the magnetic layer because of the decrease of the magnetic permeability. Although that maximum intrinsic sensitivity has been reached at high frequency, the equivalent sensitivity S_{equi} defined as the product of S_{int} by I_{ex} has been obtained at a low enough frequency in order to diminish the impedance and thus increase the electric current. Finally, at a frequency equal to 300kHz the transverse coiled GMI exhibits magnetic induction sensitivity as high as 1000V/T ($I_{ex}=8\text{mA}$ and $H_0=500\text{A/m}$) without electronic amplifiers. In comparison to the 0.7V/T ($I_{ex}=1\text{mA}$) maximum sensitivity of the Hall sensor [7].

4. PHYSICS MODEL

Qualitative micro magnetism approach

It is usual to investigate magnetic behaviour by the micro magnetic theory. In general, when both static and AC magnetic fields are imposed, the magnetic domain configuration in the ferromagnetic matter is modified due to magnetization rotation [8] and the domain wall movement mechanism. But in the simple case of the transverse coil specimen, only uniform rotation appears because of orthogonal direction of the AC and DC field to the anisotropic magnetic field. Considering an ideal transverse domain micro-structure, the solutions of the susceptibility tensor are given by the Landau-Lifshitz-Gilbert equation (2) where γ corresponds to the gyromagnetic ratio, α traduces the damping phenomenon and M_s is the saturated value of magnetization of one domain.

$$\frac{d\vec{M}}{dt} = -\gamma\mu_0\vec{M} \times \vec{H}_{eff} + \frac{\alpha}{M_s}\vec{M} \times \frac{d\vec{M}}{dt} \quad (2)$$

The effective magnetic field H_{eff} (4) is deduced from the minimizing of the free energy (3) which is the sum of magnetic anisotropy energy and the external field energy.

$$U = k_u \sin^2 \theta - \mu_0 M_s \sin(\theta) (H_0 + h_{ex}) \quad (3)$$

$$\vec{H}_{eff} = -\frac{1}{\gamma\mu_0 M_s} \frac{\partial U}{\partial \theta} \quad (4)$$

When the small alternating magnetic excitation h_{ex} created by I_{exc} is imposed, a linear solution of (2) can be obtained with respect to the DC field H_0 . In order to determine the former solution, equation (3) must be resolved with the equilibrium conditions of magnetization vector and the rotation angle θ is therefore given by the approximation relation (5) where k_θ is a fit parameter. Then magnetization M rotates until it is parallel to H_0 without a singular point at the H_k value.

$$\theta = \frac{\pi}{2} \tanh \left(k_\theta \frac{H_0}{H_k} \right) \quad (5)$$

Fig 9: Magnetic susceptibility χ_{zz} with DC field at different frequencies

Figure 9 above represents the χ_{zz} component susceptibility which has been calculated with these following fitting

parameters: $\gamma=2 \times 10^{10} \text{ m.A}^{-1}\text{s}^{-1}$; $\alpha=2$; $M_s=2 \times 10^6 \text{ A.m}^{-1}$ and $H_k=557 \text{ A.m}^{-1}$. At zero DC field the susceptibility is equal to its initial value. When the DC field reaches the magnetic anisotropic field, the susceptibility strongly decreases and becomes null.

Differential magnetic permeability

Last results have shown magnetization rotation susceptibility principle which can be determined by differential magnetic permeability measurements. Thus, from experimental results (Figure 3), magnetic permeability can be represented by expression (6) where H_{ext} , H_k , μ_{yyi} , μ_{yySat} , ω and ω_0 are respectively, the DC field, the anisotropic magnetic field, the initial and the saturated effective permeability, the current frequency and the relaxation frequency. And S_μ is the fitting slope parameter.

$$\mu_{yy} = - \frac{(0.5 * (-\mu_{yyi} + \mu_{yySat})) (\tanh(S_\mu (|H_{ext}| - H_k)) + 1) + \mu_{yyi}}{\sqrt{1 + \frac{\omega^2}{\omega_0^2}}} \quad (6)$$

Transverse coiled impedance and sensitivity

The impedance is deduced from the circulation of the electric field along the coil by considering the homogenous magnetization of the matter. Here in equation (7): N_b is the number of turns; R_b is the electric resistance of the coil, and parameters d , e_p and L are respectively the width, the thickness and the length of a ribbon. The penetration depth is illustrated by equation (8).

$$\underline{Z} = R_b + j\omega \left(\frac{N_b^2 \mu_{yy} d e_p}{L(1+j) \frac{e_p}{2\delta}} \tanh \left((1+j) \frac{e_p}{2\delta} \right) \right) \quad (7)$$

$$\delta = \sqrt{2 / (\sigma \mu_{yy} \omega)} \quad (8)$$

Consequently, the intrinsic sensitivity relation (9) is calculated from equation (7) in the case of low frequencies.

$$S_{int} = \frac{\partial \underline{Z}}{\partial H_0} = \frac{j\omega}{\sqrt{1 + \frac{\omega^2}{\omega_0^2}}} \frac{N_b^2 d e_p S_\mu (\mu_{yySat} - \mu_{yyi})}{2L \cosh(S_\mu (H_{ext} - H_k))^2} \quad (9)$$

Fig 10: Theoretical results of the transverse coiled GMI with one ribbon: Impedance and intrinsic sensitivity.

Theoretical impedance and intrinsic sensitivity are plotted

on Figure 10. The curves exhibit a good accuracy compared to the experimental results on Figure 3 and Figure 5. Nevertheless, above 300 kHz the magnetic permeability frequency behaviour requires more studies.

5. CONCLUSION

Sensor performances and physics basis of new GMI transducers have been investigated and have permitted to obtain high sensitive behaviour to weak DC magnetic field. These Coiled GMI elements can easily be made and integrated in demodulation amplitude electronic processing. Sensitivity is directly related to the derivative of the differential magnetic permeability which strongly varying at the anisotropic magnetic field. That was confirmed by using the micro magnetic approach in the case of the transverse type. The results have shown that intrinsic sensitivity can be more than 15 times higher than that of GMI sandwiches. These transducers have been studied for high sensitive space magnetometers which require robustness, low mass and low power consumption.
